**Abstract**—Although miniaturized piezoelectric transducers usually derive more power from motion than their electrostatic and electromagnetic counterparts, they still generate little power. The reason for this is that the electromechanical coupling factor is low, which means the damping force that tiny transducers impose on vibrations (when drawing power) is hardly noticeable. The single-inductor 0.35- $\mu\text{m}$  CMOS piezoelectric harvester proposed in this paper counters this deficiency by investing energy from the battery into the transducer. The idea is to strengthen the electrostatic force against which vibrations work. This way, the circuit draws more power from the transducer, up to 79  $\mu\text{W}$  from a 2.7-cm piezoelectric cantilever that is driven up to 0.25  $\text{m/s}^2$ . Of the 79  $\mu\text{W}$  drawn at 0.25  $\text{m/s}^2$  when investing 91 nJ of battery energy, the system outputs 52  $\mu\text{W}$ , which is 3.6 times more output power than the 14.5  $\mu\text{W}$  that a full-wave bridge rectifier with zero-volt diodes at its maximum power point can deliver from the same source. With 630 nW lost to the controller, power-conversion efficiency peaks at 69% when the harvester outputs 46  $\mu\text{W}$  of the 67  $\mu\text{W}$  it draws from the transducer at 0.25  $\text{m/s}^2$  when investing 0.8 nJ of battery energy.

**Index Terms**—Piezoelectric harvester, electrostatic damping force, energy investment, ambient vibration and motion, switched single-inductor ac–dc converter, switching supply, powering wireless microsensors, small miniaturized transducers.

Wireless microsensors can add energy-saving and performance-enhancing intelligence to the human body, moving mechanical systems, and other inaccessible places, not to mention difficult-to-manage infrastructures like manufacturing plants, hospitals, and military camps [1]–[4]. Unfortunately, the batteries that these small systems can afford to incorporate are tiny and, as a result, easily exhaustible. This is a challenge because sending personnel to recharge or replace batteries is often impossible or prohibitively expensive, especially when considering a large network of devices. Luckily, energy in light, heat, electromagnetic radiation, and motion is vast, environmentally safe, and inexpensive. But more importantly, harvesting ambient power eliminates the bulky "tank" that fuel cells and batteries typically require.

Of possible sources, kinetic energy in motion is attractive because vibrations are abundant in the environment. This is why piezoelectric transducers are popular today, and because they generate more power from motion under similar space constraints than their electrostatic and electromagnetic counterparts [2]–[3]. With this technology, vibrations shift the molecular structure of piezoelectric materials to separate charge and establish a voltage across the surfaces. The electrostatic force that results then reinforces the elastic force of the material to work against vibrations. This way, the device draws energy in both the mechanical domain as potential energy and in the electrical domain as charge.

In a harvesting system, the transducer in Fig. 1a converts kinetic energy in motion  $E_{KE}$  into electrical energy  $E_{EE}$ . A harvester circuit then draws what it can from  $E_{EE}$  as input energy  $E_{IN}$  to output charge energy  $E_{CHG}$  with which to replenish a battery or a storage capacitor. Internally, the alternating current  $i_{PZ}$  and parallel capacitance  $C_{PZ}$  in Fig. 1b model how charges in the transducer establish the electrostatic force that dampens vibrations [4]. Resistance  $R_{LEAK}$  represents the dielectric leakage of the transducer, which is usually insignificant.

1 Unfortunately, the alternating voltages that vibrations produce across  $C_{PZ}$  cannot charge a  
2 battery or a capacitor directly. Modern systems resort to full- or half-wave diode-bridge rectifiers  
3 for this purpose. To reduce power consumption and the threshold voltage above which these  
4 rectifiers can draw current, engineers often replace asynchronous diodes with synchronous MOS  
5 switches [5]–[8]. But still, when vibrations are weak and transducers are tiny [9]–[10],  
6 piezoelectric voltages can be so low that diode-bridge rectifiers can only extract power when  
7 their rectified outputs  $v_{RECT}$  are impractically low. This constraint limits diode-bridge networks  
8 to applications that exhibit strong vibrations or that can accommodate large transducers.

9 Interestingly, diode-bridge networks generate maximum power when  $v_{RECT}$  is half of  $v_{PZ}$ 's  
10 open-circuit amplitude  $v_{PZ(OC)}$ . This is why [11]–[12] incorporate a switching converter and a  
11 capacitor  $C_{RECT}$  that decouples the battery voltage  $v_{BAT}$  from  $v_{RECT}$  and loads  $C_{RECT}$  only to the  
12 extent that  $v_{RECT}$  stays near its maximum power point. Since vibration strength can change with  
13 time, [11]–[12] also interrupt the harvesting process to monitor  $v_{PZ(OC)}$  and adjust  $v_{RECT}$ . This  
14 approach is good for periodic vibrations whose  $v_{PZ(OC)}$  hardly changes over time because the time  
15 between sacrificial refresh cycles can be long.  $v_{PZ(OC)}$  for shock-induced and other random  
16 vibrations, however, changes from cycle to cycle, so halting the process to sense  $v_{PZ(OC)}$  is less  
17 viable in these latter cases.

18 Another limitation to diode-bridge rectifiers is that  $i_{PZ}$  must first charge  $C_{PZ}$  to  $v_{RECT}$  before  
19 the system can clamp  $v_{PZ}$  to  $v_{RECT}$  and output power. In other words,  $i_{PZ}$  loses charge energy to  
20  $C_{PZ}$  when transitioning  $v_{PZ}$  between  $-v_{RECT}$  and  $+v_{RECT}$ . [13] cuts this requirement in half by  
21 discharging  $C_{PZ}$  to ground with a switch and using  $i_{PZ}$  to raise  $v_{PZ}$  to  $-v_{RECT}$  or  $+v_{RECT}$  from  
22 ground. Better yet, [13]–[14] drain  $C_{PZ}$  into a recycling inductor  $L_{RE}$  and use the energy  
23 deposited in  $L_{RE}$  to recharge  $C_{PZ}$  in the other direction. This way, the system recycles  $C_{PZ}$ 's  
24 energy and  $i_{PZ}$  can therefore flow almost continuously into  $v_{RECT}$ . For this, though, the system  
25 requires a full-wave diode-bridge rectifier, a switching converter that decouples  $v_{BAT}$  from  $v_{RECT}$ ,

1 a rectifying capacitor, and a recycling inductor along with its synchronizing network, which  
2 combined dissipate more power and occupy more space than its non-recycling predecessors.

3 Instead, [15]–[16] let  $i_{pZ}$  energize  $C_{pZ}$  across  $i_{pZ}$ 's half cycles and use an inductor to quickly  
4 drain  $C_{pZ}$  into a battery between half cycles. This way, the system discards the full-wave diode-  
5 bridge rectifier, the rectifying capacitor, and the recycling inductor to save energy and space.  
6 Still, the electrostatic force that small transducers establish is so poor that output power is low  
7 when vibrations are weak.

8 [17]–[18] invest energy into  $C_{pZ}$  to strengthen the electrostatic force and, as a result, draw  
9 more power from vibrations. For this, though, [17]–[18] require multiple off-chip inductors and a  
10 high battery voltage. The harvester simulated in [19], briefly presented in [20], and prototyped  
11 and evaluated here, however, invests, draws, and transfers energy with one inductor, two  
12 switches, and a controller. To comprehend the mechanics of the system, Section II explains how  
13 the harvester invests energy to draw more power from weak vibrations and Section III describes  
14 the integrated circuit (IC) fabricated for this purpose. Sections IV and V then evaluate and  
15 discuss measured performance and Section VI draws relevant conclusions.

## 16 II. ENERGY-INVESTING SYSTEM

### 17 A. Role of Investment

18 Extracting power from kinetic energy in motion ultimately diminishes the effects of the  
19 propelling force. This means that harvesting energy opposes motion and, as a result, slows down  
20 the transducer. Therefore, boosting the opposing force that a transducer imposes draws more  
21 energy from movement. Except, raising this force beyond a critical threshold can damp motion to  
22 such an extent that movement ceases. Exceeding this critical damping point, however, is unlikely  
23 with small transducers because their electromechanical coupling factor is substantially low.

24 In the case of piezoelectric transducers, the charge across the piezoelectric capacitance  $C_{pZ}$   
25 establishes the electrostatic force that converts kinetic energy  $E_{KE}$  in motion into static electrical

1 energy  $E_{EE}$  [18]. This means that recycling or investing battery energy to charge  $C_{PZ}$  strengthens  
2 the damping force with which the transducer opposes motion to convert more mechanical energy  
3 into the electrical domain. To see this, consider that linear changes in  $C_{PZ}$ 's voltage  $v_{PZ}$  produce  
4 quadratic changes in  $C_{PZ}$ 's energy  $0.5C_{PZ}v_{PZ}^2$ . So pre-charging  $C_{PZ}$  to  $V_{PC}$  with energy  $E_{PC}$  or  
5  $0.5C_{PZ}V_{PC}^2$  and allowing  $i_{PZ}$  to charge  $C_{PZ}$  further to  $V_{PC} + \Delta v_{PZ}$  ultimately deposits  $C_{PZ}\Delta v_{PZ}V_{PC}$   
6 more energy than the  $0.5C_{PZ}\Delta v_{PZ}^2$  that  $i_{PZ}$  can output without  $V_{PC}$ :

$$7 \quad E_{NET} = E_{PZ(F)} - E_{PC} = 0.5C_{PZ}(V_{PC} + \Delta v_{PZ})^2 - 0.5C_{PZ}V_{PC}^2 = 0.5C_{PZ}\Delta v_{PZ}^2 + C_{PZ}\Delta v_{PZ}V_{PC}, \quad (1)$$

8 where  $E_{NET}$  is the net energy delivered and  $E_{PZ(F)}$  is  $C_{PZ}$ 's energy when  $v_{PZ}$  is  $V_{PC} + \Delta v_{PZ}$ . Note  
9 that this holds only as long as the transducer's opposing force is below the over-damping point.

### 10 *B. Proposed Energy-Investing Harvester*

11 In the proposed system in Fig. 2, switches  $M_{NPZ}$  and  $M_{PBAT}$  open across  $i_{PZ}$ 's positive half cycle  
12 to let  $i_{PZ}$  charge  $C_{PZ}$  to positive peak  $v_{PZ(PK)+}$ .  $M_{PBAT}$  then closes across investment time  $\tau_I$  to  
13 deposit battery energy into inductor  $L_H$ , the result of which is to raise  $L_H$ 's current  $i_L$  to roughly  
14 20 mA. Next,  $M_{PBAT}$  opens and  $M_{NPZ}$  closes to drain  $C_{PZ}$ 's harvested energy into  $L_H$  across  $\tau_{H+}$ .  
15  $M_{NPZ}$  remains closed until  $L_H$  depletes all its energy (when  $i_L$  is zero) back into  $C_{PZ}$  to pre-charge  
16  $C_{PZ}$  to negative pre-charge voltage  $-V_{PC}$ . In other words, the system invests battery energy and  
17 the energy harvested across  $i_{PZ}$ 's positive half cycle back into  $C_{PZ}$ , which means the transducer's  
18 electrostatic damping force is higher across  $i_{PZ}$ 's negative half cycle than across the positive  
19 counterpart.

20 After the investment process,  $M_{NPZ}$  and  $M_{PBAT}$  again open to allow  $i_{PZ}$  to charge  $C_{PZ}$  further in  
21 the negative direction. At the end of  $i_{PZ}$ 's negative half cycle, when  $v_{PZ}$  peaks at  $-v_{PZ(PK)-}$ ,  $M_{NPZ}$   
22 closes across  $\tau_{H-}$  to discharge  $C_{PZ}$  into  $L_H$ . Afterwards,  $M_{NPZ}$  opens and  $M_{PBAT}$  closes across  $\tau_{CHG}$   
23 to drain  $L_H$  into the battery  $v_{BAT}$ .

24 Since transferring energy into and out of  $L_H$  only requires 7  $\mu s$  of the 3.5-ms vibration period,  
25 the system can invest and harvest energy with just one inductor. Plus, because the switched

1 inductor does not need to clamp  $v_{PZ}$  to  $v_{BAT}$  to draw the energy harvested in  $C_{PZ}$ , the system can  
 2 raise  $V_{PC}$  well above  $v_{BAT}$  and  $v_{PZ(PK)+}$  to establish a higher damping force in the transducer. In  
 3 practice, however, the transducer's critical damping point, the conduction and gate-drive losses  
 4 that result from investing energy into  $C_{PZ}$ , and in extreme cases, the time required to invest  
 5 energy ultimately limit  $V_{PC}$ .

6 In this process, the system recycles the energy harvested  $E_{H+}$  across  $i_{PZ}$ 's positive half cycle  
 7 and draws battery energy  $E_{I(BAT)}$  to invest  $E_{PC}$  or  $0.5C_{PZ}V_{PC}^2$  into  $C_{PZ}$ .  $v_{BAT}$  therefore  
 8 supplements  $E_{H+}$  in  $E_{PC}$  and also supplies the power that conduction, gate-drive, and quiescent  
 9 losses  $E_{LOSS+}$  in the system consume to this point in the cycle:

$$10 \quad E_{I(BAT)} = E_{PC} - E_{H+} + E_{LOSS+} = 0.5C_{PZ}V_{PC}^2 - 0.5C_{PZ}v_{PZ(PK)+}^2 + E_{LOSS+}. \quad (2)$$

11 At the end of  $i_{PZ}$ 's negative half cycle,  $L_H$  delivers the portion of  $C_{PZ}$ 's energy  $0.5C_{PZ}v_{PZ(PK)-}^2$  that  
 12 the system does not dissipate as losses  $E_{LOSS-}$  to  $v_{BAT}$  as  $E_{CHG}$ :

$$13 \quad E_{CHG} = 0.5C_{PZ}v_{PZ(PK)-}^2 - E_{LOSS-}. \quad (3)$$

14 As a result,  $v_{BAT}$  receives the charge in  $E_{CHG}$  that  $v_{BAT}$  did not lose with  $E_{I(BAT)}$ :

$$15 \quad E_{NET} = E_{CHG} - E_{I(BAT)} = 0.5C_{PZ} \left( v_{PZ(PK)-}^2 - V_{PC}^2 + v_{PZ(PK)+}^2 \right) - E_{LOSS+} - E_{LOSS-}. \quad (4)$$

16 So if the effects of losses on  $v_{PZ}$  are minimal and those of damping are negligible, which is often  
 17 the case in miniaturized transducers when stimulated with weak vibrations,  $v_{PZ(PK)-}$  is roughly  
 18  $V_{PC} + v_{PZ(PK)+}$  like Fig. 2 shows.  $E_{NET}$  therefore reduces to

$$19 \quad E_{NET} = C_{PZ}v_{PZ(PK)+}^2 + C_{PZ}v_{PZ(PK)+}V_{PC} - E_{LOSS+} - E_{LOSS-}, \quad (5)$$

20 which is greater than the system can harvest when not investing energy to charge  $C_{PZ}$  to  $V_{PC}$ .

### 21 III. INTEGRATED CIRCUIT

22 The harvester proposed in Fig. 3 integrates the power switches from Fig. 2 with the controller  
 23 into a 0.35- $\mu\text{m}$  CMOS integrated circuit (IC). The 15-nF–10-M $\Omega$  transducer  $C_{PZ}$ – $R_{PZ}$ , the 330-  
 24  $\mu\text{H}$ –1.6- $\Omega$  inductor  $L_H$ , the battery  $v_{BAT}$ , and the negative-peak detector that Schottky diode  $D_{SS}$

1 and the 36-nF capacitor  $C_{SS}$  realize are off chip. The purpose of the negative-peak detector is to  
 2 establish a substrate voltage that is sufficiently low to keep the body diodes of all NFETs in the  
 3 system from inadvertently forward-biasing when  $C_{PZ}$ 's  $v_{PZ}$  falls below ground to  $-v_{PZ(PK)-}$ . The  
 4 detector, however, is not necessary when isolated NFETs are available, or when another  
 5 converter generates a negative bias voltage, as in [13]. The benefits of  $D_{SS}$  and  $C_{SS}$  over the  
 6 competing alternatives are lower power, less silicon area, and the use of a more mainstream and  
 7 less costly CMOS technology.

### 8 *A. Power Stage*

9 Power switches  $M_{NPZ}$  and  $M_{PBAT}$  in Fig. 3 are thick-oxide 15-V devices because their  
 10 interconnecting terminals swing with  $v_{PZ}$  above  $v_{BAT}$  and below ground. Since  $L_H$ 's current  $i_L$   
 11 momentarily peaks to milliamps to deliver microwatts on average to  $v_{BAT}$ , conduction losses can  
 12 be significant, so  $M_{NPZ}$ 's and  $M_{PBAT}$ 's channel lengths are minimum at 1.5  $\mu\text{m}$ . Channel widths  
 13 are high at 40 and 90  $\mu\text{m}$  to similarly reduce Ohmic losses, but not to the extent that higher  
 14 parasitic gate capacitance requires more gate-drive power than wider transistors would save with  
 15 lower conduction losses [23]. In other words, these channel widths should balance Ohmic and  
 16 gate-drive losses.

17 NMOS Driver: Still,  $-v_{PZ(PK)-}$  is so low with respect to ground that driving  $M_{NPZ}$ 's gate across  
 18  $v_{BAT}$  and  $-v_{PZ(PK)-}$  dissipates considerable power. But since  $M_{NPZ}$ 's gate  $v_{GN}$  only needs a portion  
 19 of  $v_{PZ(PK)-}$ ,  $M_{NPZ}$ 's driver  $DRV_N$  in Fig. 4 produces no more than a voltage-divided fraction of  
 20 what flying capacitor  $C_F$  samples when  $C_F$  connects across  $v_{BAT}$  and  $V_{SS}$ :

$$21 \quad V_{DRV} = (v_{BAT} + |V_{SS}|) \left( \frac{C_F}{C_F + C_{GN}} \right), \quad (6)$$

22 where  $C_{GN}$  is  $M_{NPZ}$ 's gate capacitance,  $V_{DRV}$  is the voltage that  $C_F$  ultimately drives, and  $C_F$  sets  
 23  $V_{DRV}$  to  $0.4(v_{BAT} + |V_{SS}|)$ . So when  $v_{BAT}$  is 4 V and  $-v_{PZ(PK)-}$  is  $-5.5$  V,  $|V_{SS}|$  is roughly 5.5 V and  
 24  $V_{DRV}$  is, as a result, about 3.8 V. For this,  $M_{PC}$  and  $M_{NC}$  close to charge  $C_F$  to  $v_{BAT} + |V_{SS}|$  while

1  $M_{TGND}$  grounds  $v_{GN}$  to open  $M_{NPZ}$  across  $i_{PZ}$ 's positive half cycle. Then,  $M_{PC}$ ,  $M_{NC}$ , and  $M_{TGND}$   
2 open and  $M_{PD}$  and  $M_{TD}$  close to connect  $C_F$  across  $v_{GN}$  and  $v_{PZ}$ .  $M_{NPZ}$  closes here because  $v_{GN}$  is  
3 at this point, as  $v_{PZ}$  transitions to  $-V_{PC}$ , above  $v_{PZ}$  by  $V_{DRV}$ . Then, the controller opens  $M_{PD}$  and  
4  $M_{TD}$  and closes  $M_{TPZ}$  to connect  $v_{GN}$  to  $v_{PZ}$  and, as a result, open  $M_{NPZ}$  across  $i_{PZ}$ 's negative half  
5 cycle. When  $v_{PZ}$  peaks to  $-v_{PZ(PK)}$ , the controller again closes  $M_{PD}$  and  $M_{TD}$  to close  $M_{NPZ}$  and  
6 therefore drain  $C_{PZ}$  into  $L_H$ .

7 This way, with a lower gate-voltage swing, the driver dissipates 8 of the 24 nJ that the circuit  
8 would have consumed had a conventional rail-to-rail inverter driven  $M_{NPZ}$ . In other words, the  
9 power that  $M_{NPZ}$  and its driver dissipate when gate-drive and Ohmic losses are optimally  
10 balanced for low power [23] is higher when swinging from  $V_{SS}$  to  $v_{BAT}$ . Here, as Fig. 4a shows,  
11  $M_{NPZ}$ 's gate drive is also independent of  $v_{PZ}$  and, as a result, consistent across half cycles.  $M_{NPZ}$ 's  
12 peak gate voltage is also higher than the voltage (i.e.,  $v_{BAT}$ ) that a rail-to-rail driver would have  
13 established. This higher drive helps offset the unfavorable effect that  $M_{NPZ}$ 's body effect has on  
14 its threshold voltage  $v_{TN}$  and, ultimately, on its resistance the Ohmic power it dissipates.

15 Two PFETs in series with their N-well bulks attached to their intermediate junction  
16 implement  $M_{PC}$ , half of  $M_{TPZ}$ , and half of  $M_{TGND}$  to keep their body diodes from conducting  
17 when either terminal voltage rises above the other.  $M_{TD}$ ,  $M_{TPZ}$ , and  $M_{TGND}$  are transmission gates  
18 because NFETs suffer from bulk effect to  $V_{SS}$  when  $v_{PZ}$  is positive and PFETs do not receive  
19 sufficient gate-drive voltages when  $v_{PZ}$  is negative. Because  $v_{GN}$  rises above and falls below  $v_{BAT}$   
20 by more than one PMOS threshold voltage, cross-coupled PFET pair  $M_{P1}$ – $M_{P2}$  in the high-  
21 voltage selector of Fig. 4b supplies the inverters that drive  $M_{TPZ2}$ – $M_{TPZ3}$  and  $M_{TGND2}$ – $M_{TGND3}$   
22 with the higher voltage of the two voltages:  $v_{GN}$  or  $v_{BAT}$ . With the higher voltage, the inverters  
23 can keep the PFETs off when they should remain off. Note that the non-overlapping clock and  
24 the logic gates that drive  $M_{PD}$ ,  $M_{TPZ}$ , and  $M_{TGND}$  keep adjacent switches from shorting supplies  
25 and dissipating shoot-through power.

1 PMOS Driver: Because  $M_{\text{PBAT}}$  in Fig. 3 connects to  $v_{\text{BAT}}$ ,  $M_{\text{PBAT}}$ 's gate  $v_{\text{GP}}$  only needs to reach  
2  $v_{\text{BAT}}$  and ground to open and close  $M_{\text{PBAT}}$ . This is why the supplies to the PMOS driver  $\text{DRV}_P$  in  
3 Fig. 5 are  $v_{\text{BAT}}$  and ground. Ground-connecting transistors  $M_{\text{P5b}}$  and  $M_{\text{P5d}}$  are P type to limit  
4  $M_{\text{PBAT}}$ 's and  $M_{\text{P5a}}$ 's gate drives to  $v_{\text{BAT}}$  because NFETs would have connected their gates to  $V_{\text{SS}}$   
5 and consumed, as a result, more gate-drive power. Plus, discharging their gates to ground keeps  
6 gate current from discharging  $C_{\text{SS}}$  and  $i_{\text{PZ}}$  from having to re-charge  $C_{\text{SS}}$  through  $D_{\text{SS}}$  in Fig. 3.  
7 Since  $M_{\text{P5a}}$  and  $M_{\text{P5b}}$  are large devices, separate inverter chains built with increasingly higher  
8 width-length transistors drive their gates. To keep  $M_{\text{P5a}}$  and  $M_{\text{P5b}}$  from conducting considerable  
9 shoot-through current, the first NAND gate in the series senses and waits until the other large  
10 transistor is off, the result of which is the introduction of "dead time" between transitions.

11 Ringings Suppressor: At the moment when the system opens  $M_{\text{NPZ}}$  and  $M_{\text{PBAT}}$  in Figs. 2 and 3,  
12 the switching node  $v_{\text{SW}}$  is either at  $-V_{\text{PC}}$  or  $v_{\text{BAT}}$ . This means,  $v_{\text{SW}}$ 's parasitic capacitance  $C_{\text{PAR}}$  in  
13 Fig. 6 has remnant energy, so  $L_{\text{H}}$  can drain and recharge  $C_{\text{PAR}}$  until series resistances dissipate  
14 the energy. The purpose of  $M_{\text{RS}}$  in Fig. 3 and  $M_{\text{N6a}}-M_{\text{P6b}}$  in Fig. 6 is to ground  $v_{\text{SW}}$  when  $M_{\text{NPZ}}$   
15 and  $M_{\text{PBAT}}$  open. Draining  $C_{\text{PAR}}$  suppresses the resonant oscillations that normally follow.

## 16 *B. Controller*

17 The comparator  $\text{CP}_{\text{PK}}$  in the peak-detector block of Fig. 3 senses when  $C_{\text{PZ}}$ 's  $v_{\text{PZ}}$  peaks to  
18 synchronize the system to  $i_{\text{PZ}}$ 's half cycles. When  $v_{\text{PZ}}$  rises in the positive half, for example,  $\text{CP}_{\text{PK}}$   
19 supplies current into  $R_{\text{PK}}$  to establish a positive voltage  $v_{\text{RPK}}$  across  $R_{\text{PK}}$ . But when  $v_{\text{PZ}}$  reverses  
20 and falls,  $\text{CP}_{\text{PK}}$ 's current and  $R_{\text{PK}}$ 's  $v_{\text{RPK}}$  also reverse to trip  $\text{CP}_{\text{PK}}$  and raise  $v_{\text{PK}}$ . The control logic  
21 in Fig. 7 then pulls  $v_{\text{GP(INV)}}$  high to close  $M_{\text{PBAT}}$ , and as a result, draw battery energy into  $L_{\text{H}}$ .  
22  $v_{\text{DLY}}$  in the tunable delay  $\tau_1$  in Fig. 3 then determines how long  $v_{\text{BAT}}$  energizes  $L_{\text{H}}$ . So after  $v_{\text{DLY}}$   
23 rises, the logic in Fig. 7 responds by opening  $M_{\text{PBAT}}$  when  $v_{\text{GP(INV)}}$  falls and closing  $M_{\text{NPZ}}$  when  
24  $v_{\text{GP(MON)}}$  and  $v_{\text{GGND}}$  fall, commanding the system to drain  $C_{\text{PZ}}$  into  $L_{\text{H}}$ . When  $L_{\text{H}}$ 's  $i_{\text{L}}$  is close to

1 zero, which happens when the inductor depletes, comparator  $CP_{LD}$  in Fig. 3 raises  $v_{LD}$  to disable  
2  $CP_{LD}$  and prompt the logic in Fig. 7 to raise  $v_{GPZ}$  and, in consequence, open  $M_{NPZ}$ .

3 As  $v_{PZ}$  falls in the negative half,  $C_{PK}$  continues to pull current from  $R_{PK}$  to produce a negative  
4 voltage in  $v_{RPK}$ . When  $v_{PZ}$  reverses and rises,  $C_{PK}$ 's current and  $R_{PK}$ 's  $v_{RPK}$  also reverse to trip  
5  $CP_{PK}$ , lower  $v_{PK}$ , and reset  $v_{GPZ}$  low. This closes  $M_{NPZ}$  and drains  $C_{PZ}$  into  $L_H$ . After  $\tau_{H-}$  in Fig. 3  
6 lapses,  $v_{DLY}$  transitions low to raise  $v_{GGND}$  and open  $M_{NPZ}$ . Stored energy in  $L_H$  in the form of  $i_L$   
7 then drives switching node  $v_{SW}$  above  $v_{BAT}$  until the charge-control comparator  $CP_{CHG}$  in Fig. 3  
8 trips, which then lowers  $v_{CHG}$  and raises  $v_{GP(HARV)}$ . This ultimately closes  $M_{PBAT}$  to drain  $L_H$  into  
9  $v_{BAT}$ , until  $CP_{CHG}$  senses that  $L_H$ 's  $i_L$  produces close to zero volts across  $M_{PBAT}$ . At this point,  
10  $v_{CHG}$  rises and  $v_{GP(HARV)}$  drops to open  $M_{PBAT}$  again and start another harvesting cycle.

11 Peak Detector: Peak-detecting comparator  $CP_{PK}$  in Fig. 3 consists of two identical comparators  
12  $CP_{PK+}$  and  $CP_{PK-}$  from Fig. 8. When  $v_{PK}$  is low across  $i_{PZ}$ 's positive half cycle,  $CP_{PK-}$  is off and  
13  $CP_{PK+}$  detects when  $v_{PZ}$  peaks to  $v_{PZ(PK)+}$ .  $CP_{PK+}$ 's output  $v_{O+}$  sets the latch, which in turn disables  
14  $CP_{PK+}$ , prompts the system to invest  $v_{BAT}$  energy into  $L_H$ , and then enables  $CP_{PK-}$  after about 100  
15  $\mu s$ . This 100- $\mu s$  delay keeps the comparators from tripping erroneously when  $M_{NPZ}$  and  $M_{PBAT}$   
16 switch. Across  $i_{PZ}$ 's negative half cycle,  $CP_{PK-}$  monitors  $v_{PZ}$  and trips when  $v_{PZ}$  reaches  $-v_{PZ(PK)-}$ .  
17 At this point,  $CP_{PK-}$ 's output  $v_{O-}$  resets the latch to disable  $CP_{PK-}$ , send a command to deplete  $C_{PZ}$   
18 into  $L_H$ , and enable  $CP_{PK+}$  after another deglitch period.

19 Since  $R_{PK}$  connects to ground and the voltage that  $R_{PK}$  drops is not substantial, a PMOS  
20 differential pair  $M_{P8a}-M_{P8b}$  in Fig. 8 senses  $R_{PK}$ 's  $v_{RPK}$  and feeds an NMOS mirror  $M_{N8a}-M_{N8b}$ ,  
21 and together they drive a common-source transistor  $M_{N8c}$ . Because  $M_{N8c}$  pulls  $v_{O8b}$  quickly and  
22 bias transistor  $M_{P8g}$  slews  $v_{O8b}$ , the inputs of  $CP_{PK+}$  and  $CP_{PK-}$  connect to  $C_{PK}$  and  $R_{PK}$ , so that  
23  $M_{N8c}$  pulls  $v_{O8b}$  when  $v_{PZ}$  peaks. This way, the comparators respond quickly.  $M_{P8j}$  steers an offset  
24 current into  $M_{N8a}-M_{N8b}$  when  $v_{O8b}$  is low to establish hysteresis after  $v_{PZ}$  peaks in the form of an

1 intentional input-referred offset. The purpose of the hysteresis is to keep noise in the slow analog  
2 inputs from inadvertently tripping  $CP_{PK+}$  and  $CP_{PK-}$ .

3 Tunable Delays: The SR-latches in Fig. 9 coordinate and synchronize which and when delay  
4 times  $\tau_I$  and  $\tau_{H-}$  from Fig. 3 start.  $V_{INV}$  and  $V_{HARV}$  adjust how much current flows through  $R_I$  and  
5  $R_H$  and into  $C_{RAMP}$  to set the delay times  $\tau_I$  and  $\tau_{H-}$  that  $C_{RAMP}$ 's  $v_{RAMP}$  requires to trip  $M_{N9e}$ . This  
6 way, when  $v_{PK}$  in Fig. 3 transitions high at the end of  $i_{PZ}$ 's positive half cycle, the Invest latch in  
7 Fig. 9 closes  $M_{P9c}$ – $M_{N9c}$  to steer  $R_I$ 's current into  $C_{RAMP}$ , and after  $\tau_I$ ,  $M_{N9e}$  trips and sets the  
8 output latch to generate a high end-of-delay signal  $v_{DLV}$ . Similarly, the Harvest latch prompts  
9  $M_{P9d}$ – $M_{N9d}$  to steer  $R_H$ 's current into  $C_{RAMP}$  to establish  $\tau_{H-}$ .

10  $M_{N9e}$  and  $M_{N9g}$  form a positive-feedback loop at  $v_{O9a}$  that accelerates  $v_{O9a}$ 's falling transition.  
11  $v_{O9a}$  therefore falls more quickly than  $v_{RAMP}$  rises, and the output inverters, as a result, conduct  
12 less shoot-through current during the transition.  $M_{N9e}$  does not trip until  $v_{RAMP}$  is high enough for  
13  $M_{N9f}$  to sink  $M_{N9e}$ 's 3 nA and  $M_{N9g}$ 's 30 nA. When  $M_{N9f}$  sinks more than 33 nA,  $v_{O9a}$  falls and  
14  $M_{N9g}$  opens. As a result,  $M_{N9e}$  now pulls  $v_{O9a}$  with more current, which expedites  $v_{O9a}$ 's fall.

15 Inductor Energy-Drain Sensor:  $CP_{LD}$  in Figs. 3 and 10 senses when  $L_H$  depletes by monitoring  
16 the current that  $v_{PZ}$  establishes through  $C_S$ . So as  $L_H$  drains into  $C_{PZ}$  at the end of  $i_{PZ}$ 's positive  
17 half cycle,  $v_{PZ}$  falls and  $C_S$  responds by pulling current from the input of P-type mirror  $M_{P10a}$ –  
18  $M_{P10c}$  in Fig. 10.  $M_{P10b}$  therefore generates voltage  $v_S$  across  $R_S$  that keeps  $CP_{LD}$ 's output  $v_{LD}$  low.  
19 When  $L_H$  depletes all the energy into  $C_{PZ}$ ,  $v_{PZ}$  stops falling,  $C_S$ 's current drops to nearly zero, and  
20 with no current to drive  $v_S$ ,  $v_S$  falls to zero. Since  $M_{P10c}$ 's current establishes an offset  $v_{OS10}$   
21 across  $C_{OS}$  for  $CP_{LD}$  that overwhelms  $CP_{LD}$ 's inherent offset and rises with  $v_{PZ}$ 's transition rate,  
22  $v_S$ 's fall to zero trips  $CP_{LD}$ . This raises  $v_{LD}$  and alerts the system that  $L_H$  no longer stores energy.  
23 Producing an offset  $v_{OS10}$  that is higher when  $v_{PZ}$  transitions more quickly overdrives  $CP_{LD}$ ,  
24 which accelerates  $CP_{LD}$ 's response.

1 Since  $CP_{LD}$ 's inputs hover about ground and response time is only important in one direction,  
 2  $CP_{LD}$ ,  $CP_{PK+}$ , and  $CP_{PK-}$  share the circuit architecture in Fig. 8. But because  $CP_{LD}$ 's speed  
 3 requirements differ from those of  $CP_{PK+}$  and  $CP_{PK-}$ , width-length ratios and bias currents are  
 4 different. In this case, the system enables  $CP_{LD}$  when  $M_{NPZ}$  closes and the latch in Fig. 10  
 5 disables  $CP_{LD}$  (after  $CP_{LD}$  trips to raise  $v_{LD}$ ). For a faster response,  $I_{BLEED}$ 's 1.5 nA keeps the  
 6 input mirror  $M_{P10a}$  from shutting completely. Note that  $C_S$  is so much lower than  $C_{PZ}$  that  $C_S$   
 7 hardly affects  $v_{PZ}$ .

8 Charge Control: The circuit in Fig. 11 implements the charge-control comparator  $CP_{CHG}$  in Fig. 3.  
 9 Here, gate-coupled differential pair  $M_{P11a}$ – $M_{P11b}$  senses the voltage across  $M_{PBAT}$  in Fig. 3, and  
 10 mirror  $M_{N11a}$ – $M_{N11b}$  ensures that  $M_{P11a}$ 's and  $M_{P11b}$ 's drain currents equal when  $M_{PBAT}$ 's voltage  
 11  $v_{SDP}$  or  $v_{SW} - v_{BAT}$  is zero. This way, when  $v_{SW}$  surpasses  $v_{BAT}$ ,  $M_{P11a}$ 's current exceeds  $M_{N11a}$ 's to  
 12 raise  $v_{O11a}$ , lower  $v_{CHG}$ , and close  $M_{PBAT}$ , which begins draining  $L_H$  into  $v_{BAT}$  through  $M_{PBAT}$ 's  
 13 channel. At this point,  $M_{P11e}$  raises  $v_{OS11}$  to establish an offset current  $i_{OS}$  that  $M_{P11a}$  must supply  
 14 to keep  $v_{O11a}$  high. So as  $L_H$ 's  $i_L$  drops,  $v_{SW}$  and  $v_{SDP}$  fall. When  $M_{P11a}$ 's current falls below  $M_{N11a}$   
 15 and  $M_{N11i}$ 's combined current,  $v_{O11a}$  then drops and  $v_{CHG}$  rises to open  $M_{PBAT}$  and reset both  $v_{OS11}$   
 16 and  $i_{OS}$  to zero.

17 Since  $L_H$ 's  $i_L$  raises  $v_{SW}$  quickly when  $L_H$  first starts to drain,  $M_{P11a}$  can supply considerable  
 18 current into  $v_{O11a}$ , so the circuit can close  $M_{PBAT}$  quickly. The purpose of  $i_{OS}$  is to help the other  
 19 transition, to begin transitioning  $v_{O11a}$  low when  $v_{SW}$  is slightly above  $v_{BAT}$ . Starting early gives  
 20 the circuit time to open  $M_{PBAT}$  before  $v_{SW}$  falls below  $v_{BAT}$ , which would otherwise drain energy  
 21 from  $v_{BAT}$  into  $L_H$ . But since  $M_{P11e}$  raises  $v_{OS11}$  only after  $v_{O11a}$  transitions high,  $i_{OS}$  does not  
 22 affect the rising trip point of the circuit. If  $M_{PBAT}$  opens early,  $L_H$ 's  $i_L$  raises  $v_{SW}$  to the point that  
 23  $M_{PBAT}$ 's body diode forward-biases and finishes draining  $L_H$  into  $v_{BAT}$ . The purpose of the diode-  
 24 connected stack  $M_{N11d}$ – $M_{N11e}$  is to clamp  $v_{O11a}$ . This way,  $v_{O11a}$  requires less transition time to

1 open  $M_{N11c}$  and open  $M_{PBAT}$ . After  $M_{PBAT}$  opens, the system disables  $CP_{CHG}$  to save energy and  
 2 keep remnant energy in  $L_H$  from inadvertently tripping  $CP_{CHG}$ .

### 3 *C. Bias-Current Generators*

4 The nano-amp PTAT current generator in Fig. 12 biases  $CP_{PK}$ , the tunable-delay block, and the  
 5 inductor energy-drain sensor. Here, mirror  $M_{N12a}-M_{N12f}$  ensures  $M_{P12a}-M_{P12b}$  currents match at  
 6  $I_{BIAS}$  and  $M_{P12f}$ 's current is at  $2I_{BIAS}$ . This way,  $M_{P12a}$  and  $M_{P12b}$  impress the gate-source-voltage  
 7 difference that their width-length ratios establish across  $M_{P12e}$  to bias  $M_{P12e}$  in triode [21], whose  
 8 resistance is about 18 M $\Omega$ . To avoid a zero-current state,  $M_{N12i}-M_{N12j}$  mirrors  $I_{BIAS}$  to a stack of  
 9 diode-connected PFETs that raises  $v_{START}$  when  $I_{BIAS}$  is zero, in which case the circuit steers  
 10 startup currents  $i_{ST1}$  and  $i_{ST2}$  into the PTAT bias core. As a result,  $I_{BIAS}$  is 1.2 – 3.6 nA when  
 11 measured across 2.5 – 12.5-V supplies at room temperature.

12 The micro-amp PTAT current generator in Fig. 13 is inside both  $CP_{LD}$  and  $CP_{CHG}$ . As with the  
 13 nano-amp version,  $M_{N13a}-M_{N13b}$  ensures that  $M_{P13a}-M_{P13b}$  currents match at  $I_B$ , and  $M_{P13a}-M_{P13b}$   
 14 impresses a gate-source-voltage difference across  $R_{PTAT}$  to set  $I_B$  to roughly 2  $\mu$ A at room  
 15 temperature. When disabled,  $M_{P13f}$  is open and  $M_{N13c}$  pulls  $v_{ST}$  low to charge  $C_{ST}$ . So when  
 16 enabled,  $M_{P13f}$  closes and  $v_{ST}$ ,  $M_{P13d}$ ,  $M_{P13e}$ , and  $R_{ST}$  define a current  $i_{ST}$  that flows into the PTAT  
 17 bias core to start the circuit [22].  $M_{P13c}$  mirrors  $I_B$  and pulls  $v_{ST}$  to the supply when  $I_B$  is not zero  
 18 to open  $M_{P13e}$  and shut  $i_{ST}$ . This way,  $I_B$  settles within 1  $\mu$ s under all measured conditions.

## 19 IV. MEASURED PERFORMANCE

20 Fig. 14 shows the fabricated  $1.8 \times 1.3 \text{ mm}^2$  0.35- $\mu$ m CMOS die and the prototyped  $4.2 \times 3.3 \times$   
 21  $0.16 \text{ cm}^3$  board used to test the system. Power transistors  $M_{NPZ}$  and  $M_{PBAT}$  are against the upper  
 22 edge and corners of the die to keep metal lengths in the power path short and the substrate noise  
 23 that the transistors generate away from noise-sensitive blocks. To further reduce crosstalk, the  
 24 power transistors and the analog blocks connect to the negative supply  $V_{SS}$  via separate bond  
 25 pads, bond wires, and pins. Although they all share the same substrate, "star" connecting them

1 this way reduces the impact of noise in one on the other. The HSMS-2800 Schottky diode and  
2 the 36-nF SMD capacitor that establishes  $V_{SS}$  are on the bottom side of the board. A V22b  
3 transducer from Mide Technology that integrates  $25.4 \times 3.8 \times 0.25 \text{ mm}^3$  of piezoelectric material  
4 inside a 2.7-cm cantilever attaches to the board, which a plastic bolt fixes to a 4810 mini-shaker  
5 shaker from Brüel & Kjær. A slide switch enables and disables the system and an LK-G87  
6 displacement sensor from Keyence Corporation monitored the movements of the transducer.

### 7 *A. Charging Performance*

8 As Fig. 15a shows, the prototype charges 475 nF from the vibrations that would otherwise  
9 produce open-circuit piezoelectric voltages  $v_{PZ(OC)}$  between 0.57 and 2.0 V from acceleration  
10 rates at the base of the cantilever between 0.06 and 0.21  $\text{m/s}^2$ . Since the harvester invests battery  
11 energy when  $v_{PZ}$  peaks to  $v_{PZ(PK)+}$  and charges  $v_{BAT}$  when  $v_{PZ}$  bottoms at  $v_{PZ(PK)-}$ ,  $v_{BAT}$  steps  
12 down at the end of the positive half cycle and up at the end of the period. With the investment  
13 time  $\tau_I$  fixed at 1.9  $\mu\text{s}$ , harvested output power rises with stronger vibrations to raise  $v_{BAT}$ . When  
14 vibrations are weak at 0.06  $\text{m/s}^2$ , however, the system only generates enough energy to cover the  
15 investment and losses. This is why  $v_{BAT}$  in Fig. 15a generally rises as long as accelerations are  
16 above 0.06  $\text{m/s}^2$ .

17 Although  $v_{BAT}$  still rises in Fig. 15b when  $\tau_I$  is 0.34  $\mu\text{s}$ , the investment time is so short that  
18  $v_{BAT}$  hardly invests energy. Under this condition, the system only re-invests what  $C_{PZ}$  collects  
19 across  $i_{PZ}$ 's positive half cycle to raise  $v_{BAT}$  in Fig. 15b to 3.61 V at 60 ms (and with more time,  
20 to higher voltages). With  $\tau_I$  at 1.42 and 1.82  $\mu\text{s}$ , however,  $v_{BAT}$  invests and collects more energy  
21 to rise to 3.71 and 3.72 V. Raising  $\tau_I$  to 2.53  $\mu\text{s}$  reverses the improvement because power losses  
22 at this point outpace gains from investment.

### 23 *B. Power Performance*

24 As Fig. 16a shows, the system draws up to 79  $\mu\text{W}$  of input power  $P_{IN}$  from the transducer when  
25 driven with up to 0.25  $\text{m/s}^2$  and investing 91 nJ of battery energy and delivers as much as 52  $\mu\text{W}$

1 of output power  $P_O$  to  $v_{BAT}$ . When the system only re-invests harvested power, when  $E_{I(BAT)}$  is  
2 close to nil at 0.8 nJ and vibrations are still at  $0.25 \text{ m/s}^2$ ,  $P_{IN}$  is  $67 \text{ } \mu\text{W}$  and  $P_O$  is  $46 \text{ } \mu\text{W}$ .  $P_{IN}$   
3 climbs with higher  $E_{I(BAT)}$  because the electrostatic force with which the transducer extracts  
4 power from motion rises with  $E_{I(BAT)}$ .  $P_O$ , however, does not rise to the same degree because  
5 losses in the system also climb with  $E_{I(BAT)}$ . Vibrations are so weak when  $v_{PZ(OC)}$  is 0.61 V, in  
6 fact, that  $P_O$  in Fig. 16b falls with additional battery investments. With stronger vibrations,  $v_{BAT}$   
7 recovers investments when  $v_{PZ(OC)}$  is 1.02 V and collects more energy than it invests when  $v_{PZ(OC)}$   
8 is 2.62 V.

### 9 *C. Power-Conversion Efficiency*

10 The reason power losses rise with battery investments  $E_{I(BAT)}$  is that switches consume more  
11 Ohmic power  $P_{COND}$  when they deliver more output power  $P_O$ , as Fig. 17a shows when raising  
12 vibration strength. As a result, power-conversion efficiency  $\eta_{IC}$  or  $P_O/P_{IN}$  across the IC in Fig.  
13 17b falls with higher investments.  $\eta_{IC}$ , however, rises with  $P_O$  to 66% – 69% because increases in  
14  $P_O$  outpace those of  $P_{COND}$ .  $\eta_{IC}$  drops quickly when  $P_O$  falls below roughly  $5 \text{ } \mu\text{W}$  because, while  
15  $P_{COND}$  scales with  $P_O$ , quiescent and gate-drive power  $P_Q$  and  $P_{GD}$  do not. In other words,  $P_Q$  and  
16  $P_{GD}$  are constant and dominate when  $P_{COND}$  drops, in this case, below roughly  $3 \text{ } \mu\text{W}$ .

17 Efficiency does not actually peak because conduction and gate-drive losses  $P_{COND}$  and  $P_{GD}$  in  
18  $M_{NPZ}$  and  $M_{PBAT}$  never balance across  $P_O$ . Increasing their widths, which lowers resistance and  
19  $P_{COND}$  and raises gate capacitance and  $P_{GD}$ , should yield higher efficiency. The drawback to  
20 raising  $P_{GD}$  is that vibrations must be strong enough to produce more power than  $P_{GD}$ . In other  
21 words, the threshold above which accelerations must rise to output a positive power is higher  
22 with more  $P_{GD}$ . As is,  $CP_{PK}$ , the tunable-delay block, and the nano-amp generator, which operate  
23 continuously, consume  $0.3 - 0.5 \text{ } \mu\text{W}$ , and duty-cycled blocks  $CP_{LD}$  and  $CP_{CHG}$  dissipate  $45 - 116$   
24 nW, so the system outputs power when accelerations exceed  $0.06 \text{ m/s}^2$ . Although the transducer

1 model used to simulate the system was imperfect, measured power losses follow those obtained  
2 from simulations and predicted by calculations presented in [15].

### 3 V. CONTEXT AND LIMITATIONS

4 Piezoelectric transducers generate the most power when they vibrate at their resonant frequency.  
5 Unfortunately, motion is not always consistent or periodic. Many applications, in fact, vibrate in  
6 response to shocks, or repeated impact. This means that vibration strength peaks at the onset of  
7 an event and falls with time afterwards. Because the prototype senses  $v_{PZ}$  and synchronizes the  
8 system to  $v_{PZ}$  across  $i_{PZ}$ 's half cycles, the system automatically adjusts to variable conditions.  
9 This is why tapping the bolt head of the board in Fig. 14b three times charged 475 nF in Fig. 18a  
10 to about 3.9 V. But since this system cannot adjust the battery investment automatically from  
11 cycle to cycle, and it cannot afford to lose the power necessary to transfer battery energy when  
12 vibrations are weak, the system only re-invests harvested energy in Fig. 18. As a result,  $v_{BAT}$   
13 never falls in Fig. 18b, because the battery never invests energy. In this case, when only re-  
14 investing the harvested energy,  $M_{PBAT}$  in Figs. 2 and 3 can operate like an asynchronous diode,  
15 which simplifies the controller and reduces power losses in the controller.

16 Since energy in the piezoelectric capacitance  $C_{PZ}$  rises linearly with  $C_{PZ}$  and quadratically  
17 with  $C_{PZ}$ 's open-circuit voltage  $V_{PZ(OC)}$ , and higher vibrating frequencies  $f_{VIB}$  deliver this energy  
18 more often, output power  $P_O$  naturally climbs with  $C_{PZ}$ ,  $V_{PZ(OC)}^2$ , and  $f_{VIB}$ . This, and because  
19  $C_{PZ}V_{PZ(OC)}^2f_{VIB}$  is the maximum power that a lossless full-wave diode-bridge rectifier can output  
20 [11]–[13], is why the figure of merit (FoM) in Table I is higher when  $P_O$  is high and  $C_{PZ}$ ,  $V_{PZ(OC)}$ ,  
21 and  $f_{VIB}$  are low. In this light, the energy-investing prototype presented here outputs 4 to 4.5  
22 times more power than its non-investing switched-inductor predecessor in [15].

23 Under similar conditions, this technology delivers 3.6 times more power at 52  $\mu$ W in Fig. 16a  
24 when battery-investment energy  $E_{I(BAT)}$  is 91 nJ than a full-wave bridge rectifier with zero-volt  
25 diodes at its maximum power point can at 14.5  $\mu$ W from the same source. Even when only re-

1 investing harvested energy, when  $E_{I(BAT)}$  is close to nil at 0.8 nJ, the system still outputs 3.2  
2 times more power. This means that investing battery energy in addition to the re-investment of  
3 the harvested energy outputs 13% more power than when only re-investing harvested energy.  
4 Similarly, the recycling full-wave bridge rectifier in [13] delivers more power than its non-  
5 recycling counterparts because a switched inductor re-invests harvested energy into the  
6 transducer. Still, the switched-inductor presented here delivers 20% more power than [13]  
7 because it can draw additional investment energy from the battery. Plus, while the system here  
8 adjusts to aperiodic vibrations, the rectifier in [13] with the recycling inductor cannot.

9 Investing energy in this system amounts to pre-charging the capacitance across the transducer.  
10 But because junctions and gate oxides break down at about 15 V, the system cannot invest more  
11 than this level. Plus, since the components that deliver the investment dissipate power, returns on  
12 investment must exceed losses for output power to rise. Satisfying this prerequisite is more  
13 difficult when vibrations are weak. This is why  $P_O$  in Fig. 16b falls with higher investments  
14 when vibrations are weak at  $0.07 \text{ m/s}^2$ . In other words, investing battery energy raises output  
15 power when vibrations are periodic and moderate to strong, and when power-conversion  
16 efficiency across the system is high. In the case of the prototyped system, investing battery  
17 energy no longer helps when accelerations fall below  $0.06 \text{ m/s}^2$ .

18 Ultimately, investing battery energy raises the electrostatic damping force in the piezoelectric  
19 transducer, so the system draws more power from motion. This additional force works against  
20 vibrations to reduce the displacement distance of the transducer's tip by roughly 1.3% from 634  
21 to 626  $\mu\text{m}$ , as Fig. 19 shows. Thankfully, the damping force is never high enough to reach the  
22 threshold beyond which drawn power fails to climb. In fact, the coupling factor of miniaturized  
23 transducers is so low that reaching this critical damping point is highly unlikely. The situation  
24 can change, however, when transducers are larger and better, that is to say, when coupling  
25 factors are higher.

## VI. CONCLUSIONS

The prototyped 0.35- $\mu\text{m}$  CMOS harvester presented here harnesses 79  $\mu\text{W}$  from a 2.7-cm piezoelectric cantilever to deliver 52  $\mu\text{W}$  to a battery. This is 3.6 times more power than a full-wave bridge rectifier with zero-volt diodes at its maximum power point can at 14.5  $\mu\text{W}$  from the same 0.25- $\text{m/s}^2$  vibrations. For this improvement, the system invests harvested energy collected across the positive half cycle and another 91 nJ from the battery into the piezoelectric transducer. Although returns on investments diminish when vibrations weaken because the system dissipates power when transferring the investment, investing energy still raises output power for accelerations higher than 0.06  $\text{m/s}^2$ . In other words, investing energy raises the mechanical-to-electrical energy-conversion efficiency of the transducer. This holds true as long as the system does not over-damp vibrations, which is unlikely in miniaturized transducers because coupling factors are low. Although the harvester can also harness energy from shocks, the system cannot adjust the battery investment "on the fly", so re-investing harvested energy is better in these cases. Still, many applications like motors produce periodic or semi-periodic vibrations. Factories, hospitals, and a host of other applications can therefore enjoy more benefits, because drawing more power from motion allows wireless microsensors to incorporate more intelligence.

## ACKNOWLEDGEMENT

The authors thank Bryan Legates and Linear Technology for their support and sponsorship.
